ABSTRACT

Molecular scale understanding of the structure and properties of aqueous interfaces with clays, metal (oxy-)hydroxides, layered double hydroxides, and other inorganic phases is strongly affected by significant degrees of structural and compositional disorder of the interfaces. ClayFF was originally developed as a robust and flexible force field for classical molecular simulations of such systems (Cygan, R. T.; Liang, J.-J.; Kalinichev, A. G. *J. Phys. Chem. B* **2004**, *108*, 1255–1266). However, despite its success, multiple limitations have also become evident with its use. One of the most important limitations is the difficulty to accurately model the edges of finite size nanoparticles or pores rather than infinitely layered periodic structures. Here we propose a systematic approach to solve this problem by developing specific metal-O-H (M-O-H) bending terms for ClayFF, $E_{\text{bend}} = k(\theta - \theta_0)^2$ to better describe the structure and dynamics of singly protonated hydroxyl groups at mineral surfaces, particularly edge surfaces. Based on a series of DFT calculations, the optimal values of the Al-O-H and Mg-O-H parameters for Al and Mg in octahedral coordination are determined to be $\theta_{0,\text{AlOH}} = \theta_{0,\text{MgOH}} = 110^\circ$, $k_{\text{AlOH}} = 15 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$, and $k_{\text{MgOH}} = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$. Molecular dynamics simulations were performed for fully hydrated models of the basal and edge surfaces of gibbsite, $\text{Al}(\text{OH})_3$, and brucite, $\text{Mg}(\text{OH})_2$, at the DFT level of theory and at the classical level, using ClayFF with and without the M-O-H term. The addition of the new bending term leads to a much more accurate representation of the orientation of O-H groups at the basal and edge surfaces. The previously observed unrealistic desorption of OH_2 groups from the particle edges within the original ClayFF model is also strongly constrained by the new modification.

INTRODUCTION

Fundamental molecular-scale understanding of the processes occurring at mineral-water interfaces is of great importance for solving many geochemical, environmental, and technological problems.^{1,2} Clay minerals attract special attention in this context.³ They are hydrous layered aluminum silicates usually in the form of ultrafine-grained (micro to nanoscale) crystallites. Their crystal structure consists of tetrahedral (T) silicate sheets and octahedral (O) oxyhydroxide sheets, either in a 1:1 (T-O) or 2:1 (T-O-T) ratio. Isomorphic substitutions in tetrahedral and octahedral sheets (typically, Al for Si and Mg for Al, respectively) produce a wide diversity of clay mineral structures and compositions. The amount of isomorphic substitutions determines the total negative layer charge of the clay structures that is compensated by the presence of cations in the interlayer space and controls the ability of clay interlayers to hydrate and swell at specific relative humidity levels. The octahedral sheets of clays are traditionally considered to be their structural backbone, with their compositional and structural features serving as the major criteria for their identification.³ The capacity of clays to adsorb and immobilize extraneous species as well as their chemical stability explain wide industrial use of clays and makes them ideal candidates for a number of important applications (e.g., deep geological waste disposal, decontamination, and heterogeneous catalysis).⁴

Many of the most widely used experimental techniques to characterize clay minerals (vibrational spectroscopy, NMR, neutron scattering/diffraction, X-ray absorption/diffraction spectroscopies, and atomic force microscopy)⁴ can provide significant insight regarding the structure and dynamical behavior of these materials, but it is often difficult to interpret these experimental data without having a detailed molecular-scale picture of these systems in mind. At the same time, computational molecular modeling methods, such as Monte Carlo or molecular dynamics (MD) simulations, are capable of providing direct quantitative

1
2
3 information on a fundamental molecular scale about numerous interfacial and bulk properties
4
5 of such materials.⁵ In classical simulations, interatomic forces are derived from a set of
6
7 interaction energy terms often called force fields (FFs). Contrary to methods based on
8
9 quantum mechanics, FFs do not treat the electronic effects explicitly, enabling the simulation
10
11 of very large systems ($\sim 10^6$ atoms) and long simulation time ($\sim 10^{-6}$ s). However the
12
13 successful application of such classical simulation methods depends heavily on the quality of
14
15 the FFs, whose parameterization is usually based on an empirical fit of various properties of
16
17 materials (e.g., thermodynamic, structural, spectroscopic) to available experimental data
18
19 and/or to results of quantum chemical calculations.
20
21

22
23 The development of FF parameters always involves a compromise between accuracy
24
25 and transferability. Several implementations of fully flexible FF models specifically designed
26
27 for clays and related materials have been developed in the last two decades.⁶⁻¹³ Most of these
28
29 models incorporate explicit valence (bonded) parameters, and their number and complexity
30
31 often restricts their applicability to a relatively limited range of well-defined crystal structures.
32
33 ClayFF¹ was initially constructed to overcome this impediment by principally relying on
34
35 electrostatic terms and a relatively small number of simple nonbonded Lennard-Jones
36
37 parameters (to describe van der Waals interactions). Partial charges were derived from a
38
39 Mulliken population analysis and an electrostatic potential fitting method from DFT (GGA)
40
41 single-point calculations. Lennard-Jones parameters were assigned to metal (M) atoms by
42
43 fitting the calculated crystallographic parameters to experimentally derived ones. The
44
45 parameterization was based on a number of simple oxides, hydroxides, and oxyhydroxides
46
47 with experimentally well-defined structures¹ and has since proven to be transferable to a wide
48
49 range of inorganic crystals, including clays, layered double hydroxides, zeolites, cement
50
51 phases, etc.^{5,14,15}

1
2
3 Bulk crystal properties (lattice parameters, density, basal spacing, and bond distances)
4
5 of various clay structures obtained from ClayFF were found to agree very well with
6
7 experimental data.¹ The cleavage of the layered clay structure to expose the basal surface of a
8
9 model clay platelet does not involve any bond breaking, logically enabling direct simulations
10
11 of basal interfaces using the FF parameters developed to reproduce the bulk structure.⁵ In
12
13 contrast, cleavage of the structurally complex crystal edge surfaces leaves dangling bonds. As
14
15 a consequence, models of neutral surfaces are obtained through nondissociative and
16
17 dissociative H₂O sorption, otherwise known as physisorption and chemisorption of water at
18
19 the surface, respectively. However, real clay platelets in nature have finite sizes—their surface
20
21 charge depends on pH¹⁶⁻¹⁸—and many important physical-chemical processes occur
22
23 predominantly at their edges or are specific to their edges. Indeed, pH-dependent
24
25 mineral-water reactive processes occur at the edges, such as flocculation,^{19,20} crystal growth
26
27 and dissolution,²¹⁻²⁵ as well as physical and chemical sorption.²⁶⁻³⁵ Because of such a
28
29 complexity, there is no reason to believe *a priori* that the FF parameters fitted to reproduce
30
31 bulk crystal structures will be directly applicable to edge surfaces, even if a few simulations
32
33 report attempts to model edge surfaces with ClayFF.³⁶⁻⁴⁶

34
35
36
37
38 Two recent studies reported direct comparisons between the results of edge surface
39
40 modeling of pyrophyllite using ClayFF and DFT calculations with the GGA approximation.
41
42 Martins et al.⁴⁴ found deviations of ClayFF with respect to the DFT results ranging from 3 to
43
44 30% in terms of surface energies of various edge cleavages and terminations. However,
45
46 neither the presence of interfacial water nor dynamical effects were accounted for in the
47
48 comparison. Newton and Sposito⁴⁵ compared metal-O (M-O) distances at the hydrated clay
49
50 edge derived from classical MD using ClayFF with DFT calculations⁴⁷ and found an
51
52 underestimation of Si-O distances by 2-5% and an overestimation of Al-O distances by 1-5%.
53
54 To our knowledge, no comparison between the results of classical (ClayFF) and quantum
55
56
57
58
59
60

1
2
3 chemical calculations in terms of the structure and hydrogen bonding at the hydrated edge
4
5 surface has yet been made.

6
7 Yu et al.⁴⁸ observed at moderate temperatures an unrealistic thermodynamic instability
8
9 of the (1 $\bar{1}$ 0) edge surface of hydrotalcite, Mg₆Al₂(OH)₁₆CO₃ · 4H₂O, simulated with ClayFF.
10
11 They proposed to modify the original parameterization by a re-adjustment of partial atomic
12
13 charges on the basis of comparison with their DFT calculations and by adding to ClayFF a
14
15 new bending term for the Mg-O-H group. These modifications produced a better agreement
16
17 with the DFT results in terms of surface energy for the systems of interest. Following this
18
19 approach, Zeitler et al.⁴⁹ parameterized the Mg-O-H bending term using as models the bulk
20
21 crystal and the basal and edge surfaces of brucite, Mg(OH)₂. They obtained a very good
22
23 agreement with DFT (GGA) results for the Mg-O-H angle distributions and the vibrational
24
25 density of states.
26
27
28

29
30 The objective of the present work is to re-evaluate the Mg-O-H bending term
31
32 parameterization in application to hydrated edge surfaces of brucite, and to systematically
33
34 extend this approach to the Al-O-H bending term parameterization using the bulk crystal and
35
36 the hydrated basal and edge surfaces of gibbsite, Al(OH)₃. In addition, we provide a detailed
37
38 comparison of the structural and dynamic properties of hydrated brucite and gibbsite edge
39
40 surfaces, derived from classical molecular dynamics (C-MD) simulations using the original
41
42 ClayFF (ClayFF-orig), the modified ClayFF of the present work (ClayFF-MOH), and DFT
43
44 molecular dynamics (DFT-MD) simulations in terms of metal-O-H angular distributions,
45
46 hydroxyl group orientations, and the topology of the inter-surface and surface-water
47
48 H-bonding networks formed at various surfaces. With the octahedral structures of brucite and
49
50 gibbsite representing the principal backbones of many clay minerals, our results will lead to a
51
52 greatly improved classical FF description of clay particle edges.

STRUCTURAL MODELS

Brucite

The structure of brucite, the only existing polymorph of magnesium hydroxide, $\text{Mg}(\text{OH})_2$, consists of stacking layers built up by edge-sharing $\text{Mg}(\text{OH})_6$ octahedra. Following the work of Zeitler et al.,⁴⁹ the bulk crystal, its hydrated basal surface and $(1\bar{1}0)$ edge surface are considered here. The initial bulk structural model of brucite was based on the experimental X-ray diffraction data, which provides unit cell parameters of $3.15 \times 3.15 \times 4.77 \text{ \AA}^3$, $\alpha = \beta = 90^\circ$, $\gamma = 120^\circ$ trigonal symmetry.⁵⁰ To facilitate the analysis, the bulk cell was orthogonalized by redefining the \mathbf{a} and \mathbf{b} lattice vectors into $\mathbf{a}^* = \mathbf{a} - \mathbf{b}$ and $\mathbf{b}^* = \mathbf{a} + \mathbf{b}$, resulting in a $5.46 \times 3.15 \times 4.77 \text{ \AA}^3$ orthorhombic cell of twice the volume of the unit cell, used as a basis for constructing the simulation supercells. The supercells were built by repeating the unit cells in all three special directions, with two different sizes: small supercells intended for the parameterization stage and DFT-MD runs and large supercells for the classical MD runs. A $2 \times 3 \times 2$ supercell was used for the small bulk model and the basal surface models. In our test calculations a brucite edge model with two layers produced excessively ordered interfacial water structure at $T = 300 \text{ K}$, therefore a larger $2 \times 3 \times 3$ supercell was subsequently used.

Gibbsite

The structure of gibbsite, the most stable polymorph of aluminum hydroxide, $\text{Al}(\text{OH})_3$,⁵¹⁻⁵³ is formed by stacking layers built up by edge-sharing $\text{Al}(\text{OH})_6$ octahedra. The initial bulk model of gibbsite was based on experimental neutron diffraction data, which provides unit cell parameters of $8.68 \times 5.08 \times 9.74 \text{ \AA}^3$, $\alpha = \gamma = 90^\circ$, $\beta = 94.54^\circ$ monoclinic

1
2
3 symmetry.⁵⁴ As proven experimentally^{55,56} and confirmed theoretically,⁵¹ gibbsite hydroxyl
4
5 groups adopt two different orientations in the bulk: in the (001) plane (OH_{ip}), and along the
6
7 [001] direction (OH_{op}). Among the possible edge surfaces, the (100) gibbsite surface, which is
8
9 the one observed experimentally,⁵⁷ was studied here in addition to the bulk crystal and basal
10
11 surfaces. The gibbsite supercells consisted of $1 \times 2 \times 1$ and $3 \times 5 \times 3$ crystallographic unit cells,
12
13 respectively, for small and large structural models, and a $2 \times 4 \times 2$ supercell was used for the
14
15 DFT cell optimization.
16
17

18 19 **Crystal cleavage and edge termination**

20
21 The basal and edge cleavages of the two bulk metal hydroxides produce two symmetric
22
23 surfaces (Figures 1 and 2). As a consequence, the properties of the two surfaces are
24
25 statistically equivalent. The brucite ($1\bar{1}0$) edge cleavage results in 2 broken Mg-O bonds per
26
27 unit cell resulting in 1 Mg atom coordinated to 5 OH groups instead of 6 OH groups in the
28
29 bulk and 1 OH group coordinated to 2 Mg atoms instead of 3 Mg atoms in the bulk. The
30
31 gibbsite (100) edge cleavage results in 3 broken Al-O bonds per unit cell, leaving 2 Al atoms
32
33 each coordinated to 5 OH groups (instead of 6 OH groups in the bulk) and 1 OH group
34
35 coordinated to 1 Al atom instead of 2 Al atoms in the bulk. To keep the mineral slab
36
37 charge-neutral, the dangling bonds were satisfied by chemisorption or physisorption of water
38
39 molecules.
40
41
42
43

44 We determined the energies of desorption of a single H_2O molecule from a
45
46 $\text{Mg}(\text{OH})(\text{OH}_2)$ brucite edge site and from a $\text{Al}(\text{OH})(\text{OH}_2)$ gibbsite edge site to be +25.9 and
47
48 +41.9 $\text{kcal}\cdot\text{mol}^{-1}$, respectively (Table 1). Liu et al.⁵⁸ calculated the free energy of desorption
49
50 of one water molecule from a $\text{Al}(\text{OH}_2)(\text{OH}_2)$ site—the protonated form of $\text{Al}(\text{OH})(\text{OH}_2)$ —to
51
52 liquid water at $T = 300$ K to be +10 $\text{kcal}\cdot\text{mol}^{-1}$. The value of the energy of the OH_2 desorption
53
54 at 0 K for our dry gibbsite edge surface is +20.0 $\text{kcal}\cdot\text{mol}^{-1}$ (Table 1). The difference is
55
56
57
58
59
60

presumably due to the stabilizing interactions of a water molecule in liquid water and to all the entropic effects.

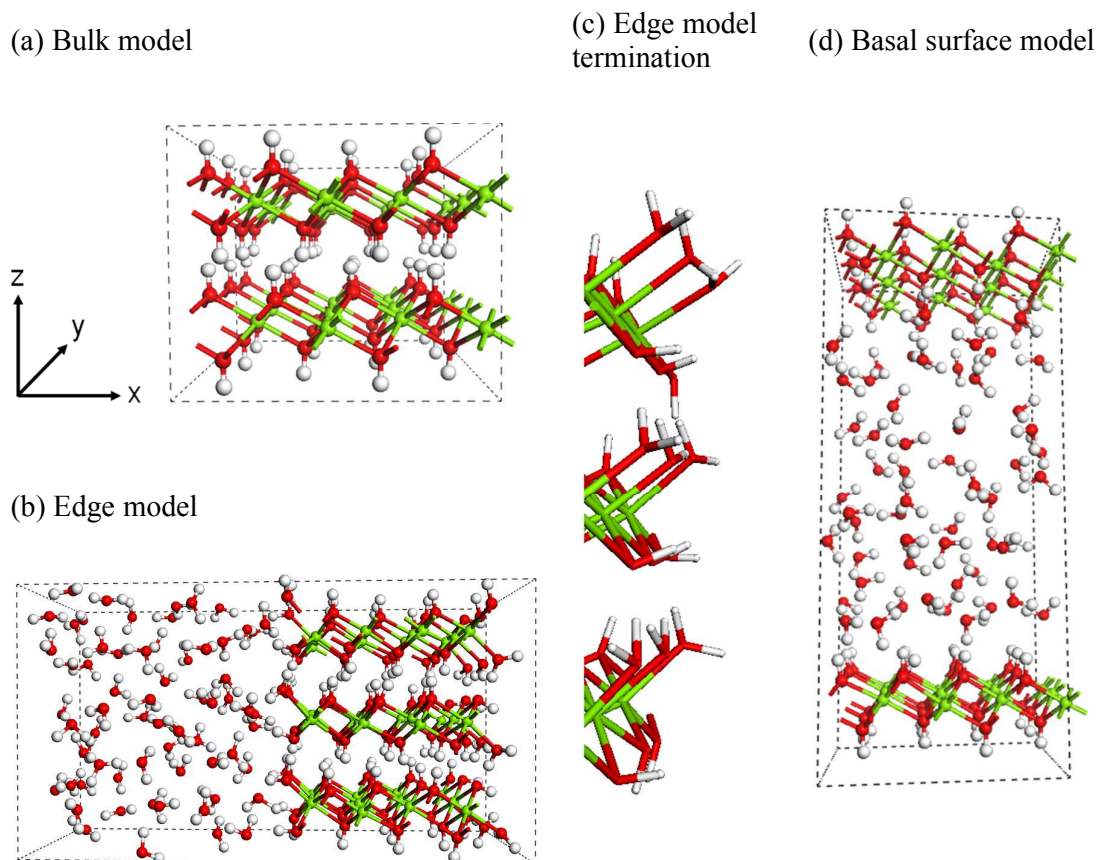

By comparing calculated energies of desorption between the vacuum and hydrated systems, and under a reasonable assumption that the effects of hydration and temperature have the same order of magnitude for all of these surfaces, we can safely predict that the free energy of desorption of one water molecule from a brucite or gibbsite $M(\text{OH})(\text{OH}_2)$ site for a hydrated surface at 300 K is at least $+10 \text{ kcal}\cdot\text{mol}^{-1}$, which justifies the termination of all the edge surfaces by one OH group and one OH_2 group at ambient temperature.

Table 1. Energies of desorption at 0 K in vacuum of a water molecule from the brucite and gibbsite edge surfaces using DFT calculations,^[1] $\text{kcal}\cdot\text{mol}^{-1}$.

	Brucite ($1\bar{1}0$) edge	Gibbsite (010) edge	
Model A	18 $\text{Mg}(\text{OH})(\text{OH}_2)^{[2]}$	8 $\text{Al}(\text{OH})(\text{OH}_2)^{[2]}$	7 $\text{Al}(\text{OH})(\text{OH}_2)$ 1 $\text{Al}(\text{OH}_2)(\text{OH}_2)$
Model B	17 $\text{Mg}(\text{OH})(\text{OH}_2)$ 1 $\text{Mg}(\text{OH})$	7 $\text{Al}(\text{OH})(\text{OH}_2)$ 1 $\text{Al}(\text{OH})$	7 $\text{Al}(\text{OH})(\text{OH}_2)$ 1 $\text{Al}(\text{OH}_2)$
$E_B + E_{\text{H}_2\text{O}} - E_A$	25.9	41.9	20.0

^[1] Model B was obtained from model A by removing one of the metal-coordinated OH_2 groups. Models were relaxed with a short 3 ps *NVT*-ensemble MD run at $T = 350 \text{ K}$ followed by geometry optimizations. Energies in $\text{kcal}\cdot\text{mol}^{-1}$. $E_{\text{H}_2\text{O}}$ is the energy of an isolated water molecule.

^[2] Models used in subsequent DFT calculations.

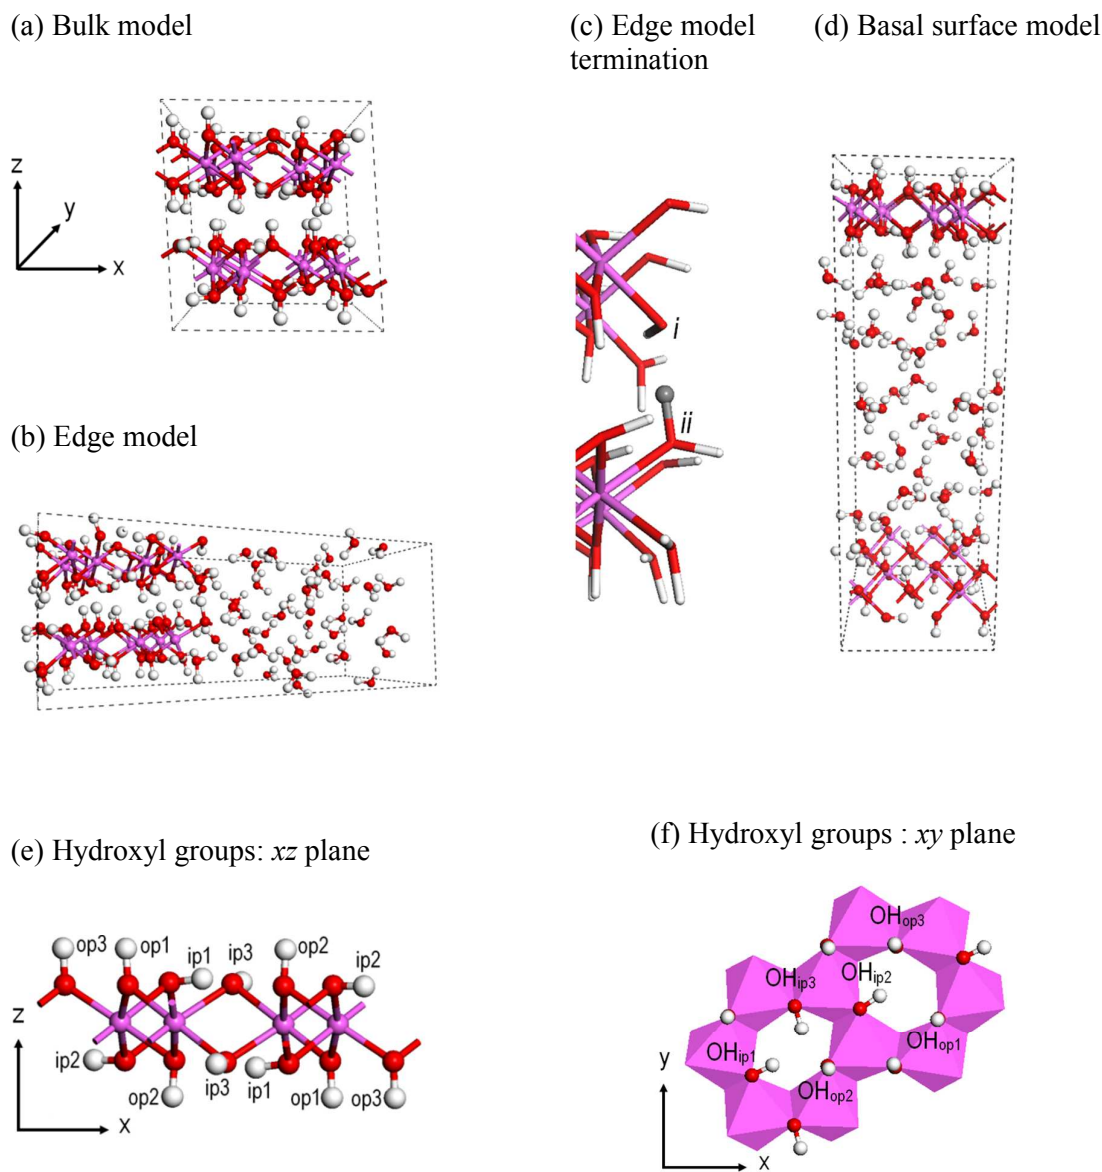

Figure 2. Gibbsite small models and hydroxyl groups types. (a) Bulk model obtained by DFT geometry optimization. (b)-(d) DFT-MD snapshots. The models are oriented according to the coordinate system shown in (a). H₂O molecules not coordinated to Al atoms are hidden in (c) for clarity. The proton in gray was bonded to the atom O_i at $t = t_0$ and was transferred to the atom O_{ii} during the DFT-MD run. The six types of hydroxyl groups oriented in the basal plane (OH_{ip}, in-plane) and out of the basal plane (OH_{op}, out-of-plane) are shown in (e) and (f) for the structures obtained by DFT geometry optimizations.

METHODS

DFT

Periodic DFT calculations used the generalized gradient approximation (GGA) with the PW91 functional, for consistency with the previous parameterizations.^{1,49} The PW91 results agree well with experimental data in terms of the brucite cell parameters, fractional cell coordinates (relative errors of, respectively, 1.1% and 1.4%), and vibrational frequencies of the crystals (within 10 cm^{-1}).^{59,60} A comparison of the cell parameters and M-O bond lengths between the dispersion-corrected⁶¹ PW91 results and experimental data for four clay minerals containing brucite- or gibbsite-like sheets, shows only differences smaller than 0.5% and 1.0%, respectively.⁶²

It is known that the simulation results with GGA functionals PW91 and PBE (essentially, a simplified version of PW91⁶³) are very close in terms of the bulk properties of clay minerals⁶² and bulk water structure.⁶⁴ It is also known that PW91 and PBE functionals produce overstructured bulk water, which is especially apparent when considering the height of the first peak of the radial distribution function $g_{\text{OO}}(r)$, and Grimme et al. dispersion corrections^{61,65} do not significantly improve on this aspect.^{66,67} In our DFT calculations, we used the DFT-D3 correction of Grimme et al.⁶⁵ The Gaussian and plane waves (GPW) scheme⁶⁸ was used here with a split-valence double-zeta basis set using a single set of polarization functions,⁶⁹ Goedecker-Tetter-Hutter pseudopotentials,⁷⁰ and a plane wave cutoff of 350 Ry for the density grid. Together with the cutoff, additional GPW settings (relative cutoff, SCF convergence criterion, precision in the calculation of the Kohn-Sham matrix) enabled a small error in the calculated forces ($< 10^{-4}$).

In DFT calculations the wavefunction was sampled at the Γ point, which allowed for a reasonable accuracy when the sizes of the mineral models are considered. For the parameterization calculations using small models, at least 15 \AA of vacuum was added to all

surface models to ensure the interaction of the platelet with its periodic image was negligible. For the MD simulations, a water slab was added instead to the platelet with respective widths of 15 Å and 30 Å for small and large structural models. The CP2K software⁶⁸ was used for all DFT calculations.

Table 2. Force Field Parameters

Nonbonded ^[1] : $E_{\text{nonbonded}} = \frac{q_i q_j}{4\pi\epsilon_0 r} + 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r}\right)^{12} - \left(\frac{\sigma_{ij}}{r}\right)^6 \right]$

^[1] Parameters of Cygan et al.¹; $\sigma_{\alpha\beta} = \frac{1}{2} (\sigma_\alpha \sigma_\beta)$ and $\epsilon_{\alpha\beta} = (\epsilon_\alpha \epsilon_\beta)^{1/2}$.

^[2] Two different sets were parameterized by Greathouse et al. for dioctahedral and trioctahedral clays,⁷¹ and the set for trioctahedral clays was found to be optimal here.

Force field parameters

All FF parameters except for the M-O-H bending terms are presented in Table 2. Nonbonded parameters were taken from the original ClayFF parameterization.¹ The original harmonic O-H-bond terms for the metal hydroxyl groups were replaced here with a more accurate Morse potential.⁷¹ Water molecules—including the OH₂ groups attached to the M atoms—are described by the SPC model⁷² with O-H bond stretching and H-O-H angle bending terms.⁷³ Because of the potential desorption of OH₂ groups, the M-O-H bending term is only applied to OH groups.

Parameterization of the metal-O-H bending term

The bending term to be parameterized has the form of $E_{\text{bend}} = k (\theta - \theta_0)^2$, where θ is the \angle MOH angle. Its parameterization consisted of finding the values of the force constant k and the equilibrium angle θ_0 , which minimized the differences between the DFT and classical ClayFF-MOH results. In the current work the following approach was used to define the optimization criteria and to determine the bending term parameters that minimize their values.

(i) Using DFT, Γ -point vibrational modes were calculated after a local geometry optimization.

(ii) Using ClayFF-MOH, a local geometry optimization was performed starting from the DFT-optimized structure, followed by the calculation of Γ -point vibrational modes. The geometry optimization and the calculation of vibrational modes were performed with the GULP software⁷⁴ for every value of θ_0 within the 90-130° range ($\delta\theta = 1^\circ$), and for every value of k within the 0-40 kcal·mol⁻¹·rad⁻² range ($\delta k = 1$ kcal·mol⁻¹·rad⁻²), while all other ClayFF parameters were kept fixed.

1
2
3 (iii) From the final structures and vibrational normal modes obtained for every pair of
4 parameters (θ_0 , k), absolute differences between DFT- and ClayFF-MOH-derived properties
5 were calculated, in terms of wavenumbers and in terms of O-H orientations. The procedure is
6 further detailed in the Supporting Information.
7
8
9

10
11 Finally, the model surfaces used in the static calculations were dry (basal surface) or
12 hydrated by only one water layer (edge surface). Whereas the consideration of energy minima
13 at $T = 0$ K for bulk solids is acceptable, the surface OH groups and the effect of the presence
14 of liquid water on the surface create disorder, thus additional entropic effects. Therefore, the
15 values of the parameters derived from the static calculations are informative but may not be
16 necessarily optimal when thermodynamic effects are included. In the simulations, a few other
17 sets of (θ_0 , k) values were also tested along with the optimal ones.

28 **Molecular dynamics**

29
30
31 Molecular dynamics (MD) simulations were performed at $T = 300$ K using a time step
32 of 0.5 fs ensuring good sampling of the dynamics of hydrogen (H) atoms. Born-Oppenheimer
33 molecular dynamics combined with DFT using the GGA approximation (DFT-MD) were
34 used in the simulations of the small structural models, and implemented with the CP2K
35 software.⁶⁸ DFT-MD simulations at a temperature higher than $T = 300$ K could limit the
36 tendency to form overstructured liquid water at $T = 300$ K by the PW91 and PBE
37 functionals,^{67,75} but the mineral platelet and specifically the surface hydroxyl groups would
38 obviously be also affected by this increase in temperature, which is problematic here since we
39 intend to directly compare the results of DFT-MD and C-MD simulations. The values of the
40 GPW-related settings allowed for a good conservation of the constant of motion (drift smaller
41 than 5×10^{-7} Ha·ps⁻¹ per atom). C-MD simulations using ClayFF with and without the M-O-H
42 bending term were used to simulate both the small and the large cells of brucite and gibbsite,
43 using the LAMMPS software.⁷⁶

1
2
3 The lattice dimensions—and the β angle for monoclinic cells—of the large bulk cells
4
5 were relaxed using *NPT*-ensemble C-MD simulations at $P = 1$ bar during 250 ps using the
6
7 Nose-Hoover chains thermostat⁷⁷ and the Parrinello-Rahman barostat.⁷⁸ The small bulk cells
8
9 were relaxed using DFT cell optimizations. For small surface models, the dimension
10
11 perpendicular to the surface was relaxed by performing *NPT*-ensemble DFT-MD for 10 ps.
12
13 For large basal surface models, the dimension perpendicular to the surface was relaxed by
14
15 performing *NPT*-ensemble DFT-MD for 100 ps. For large edge models, an *NVT*-ensemble
16
17 MD pre-equilibration run was first performed at $T = 200$ K for 100 ps to avoid initial layer
18
19 distortion, desorption of OH groups and excessive desorption of OH₂ groups, which was
20
21 otherwise observed with classical simulations when a non-equilibrated edge model was
22
23 directly subjected to a temperature of $T = 300$ K. Then the dimension of the edge model cell
24
25 perpendicular to the surface was relaxed by performing *NPT*-ensemble C-MD for 1 ns, during
26
27 which the coordination state of the metal atoms by OH₂ groups reached equilibrium. The
28
29 equilibrium average cell dimensions and angles were then assigned to the cells for the
30
31 following simulations. After a final equilibration of atomic positions and velocities by
32
33 performing *NVT*-ensemble MD for 10 ps (DFT-MD) and 100 ps (C-MD), production runs
34
35 were performed in the *NVE* ensemble for 100 ps (C-MD) and 40 ps (DFT-MD), collecting
36
37 atomic positions and velocities every 1 fs. The trajectories of the *NVE*-ensemble simulations
38
39 were initiated from the last configurations of the *NVT*-ensemble MD trajectories with the
40
41 velocities rescaled at $T = 300$ K. During the course of the *NVE*-ensemble simulations, the
42
43 effective average temperature remained constant, taking a value between 295 and 305 K. The
44
45 DFT-MD simulations of gibbsite edge surfaces, subject to proton hopping, were extended up
46
47 to 100 ps.
48
49
50
51
52

53
54 To account for a possibility of dehydroxylation, Zeitler et al.⁴⁹ proposed a “nonbonded
55
56 three-body” M-O-H bending term, which was derived for the implementation within
57
58
59
60

1
2
3 LAMMPS. It was switched on only if certain minimum M-O and M-H distance criteria were
4
5 satisfied. In the current work we applied the same term to all M-O-H groups unconditionally,
6
7 based on the initial optimized structures. Indeed, even with a selection of the optimal cutoff
8
9 criteria, the succession of activations and deactivations of the term often led to a drift of the
10
11 total energy, apparent in *NVE*-ensemble simulations. Of course, the permanent activation of
12
13 the term is only valid if there is no actual dehydroxylation in the course of the simulation run,
14
15 which was the case for gibbsite and brucite edge surfaces at $T = 300$ K.
16
17

18
19 The average bulk lattice parameters from MD runs were compared with experimental
20
21 values. To evaluate the effect of the bending term on the intrinsic structure and dynamics of
22
23 hydroxyl groups, distributions of the \angle MOH angle and the O-H bond orientation were
24
25 calculated.
26
27

28 29 **RESULTS AND DISCUSSION**

30 31 **Static calculations**

32
33 The proposed approach for the parameterization was first applied to brucite models
34
35 (bulk crystal and basal surface) in order to compare the results with the earlier calculations of
36
37 Zeitler et al.⁴⁹ Subsequently, the method was used for the edge surface of brucite, and the bulk
38
39 crystal, the dry basal surface, and the edge surface of gibbsite.
40
41
42

43
44 To estimate the optimal values of the equilibrium angle θ_0 and the force constant k ,
45
46 absolute differences between DFT and ClayFF-MOH results were plotted against the two
47
48 parameters in the form of heat maps, where θ_0 and k are the two dimensions of the map and
49
50 the differences are represented by a color range. They are presented in Section I of the
51
52 Supporting Information (Figures S1-S6). Globally, the optimal areas are large enough to
53
54 allow reasonable compromises between different structural models in the selection of the final
55
56
57
58
59
60

1
2
3 parameters, and for an integer precision in the selected values of the parameters to be
4
5 sufficient.

6
7 A θ_0 value of 110° is a good compromise for all the gibbsite models, together with a
8
9 force constant of $k = 15 \text{ kcal}\cdot\text{mol}^{-1}$ (Figures S1-S3). The experimental $\angle\text{AlOH}$ value in the
10
11 bulk is unknown, since the structural studies of the gibbsite bulk crystal were limited to X-ray
12
13 diffraction, a technique that does not precisely locate the H atoms. From our DFT-MD studies
14
15 the average $\angle\text{AlOH}$ in the bulk is 116° , therefore the performance of ClayFF-MOH with
16
17 $\theta_{0,\text{AlOH}} = 110^\circ$ was compared to that of ClayFF-MOH with $\theta_{0,\text{AlOH}} = 116^\circ$ in terms of the
18
19 MD-derived structural properties.
20
21
22

23
24 As far as the brucite models are concerned, in terms of $\langle|\Delta v|\rangle$ (Eq. S2) the optimal force
25
26 constant is clearly lower than the one for gibbsite (Figures S4–S6), the value
27
28 $k = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ being a reasonable choice for the Mg-O-H term. This value is in
29
30 agreement with those found by Zeitler et al.⁴⁹ (5.08 and $5.81 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ for the bulk and
31
32 the basal surface, respectively) and with their final retained value of $6.35 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$,
33
34 originally selected by Yu et al.⁴⁸ The equilibrium angle can be chosen the same as for the Al-
35
36 O-H term, i.e. $\theta_{0,\text{MgOH}} = \theta_{0,\text{AlOH}} = 110^\circ$. The performance of the ClayFF-MOH
37
38 parameterization with $\theta_{0,\text{MgOH}} = 110^\circ$ and $\theta_{0,\text{MgOH}} = 120^\circ$ was compared in terms of
39
40 MD-derived structural properties. The latter value was used by Zeitler et al.⁴⁹ and Yu et al.⁴⁸
41
42 because it is the value of $\angle\text{MgOH}$ obtained by neutron diffraction.⁷⁹
43
44
45

46
47 Since the value of $\theta_0 = 100^\circ$ is in the range of acceptability for all brucite and gibbsite
48
49 models, its performance was also tested alongside the aforementioned θ_0 values. In the
50
51 following C-MD results obtained with ClayFF-MOH, the values of the force constants are
52
53 fixed ($k_{\text{MgOH}} = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$, $k_{\text{AlOH}} = 15 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$) and “ClayFF-MOH-X” stands
54
55 for “ClayFF-MOH with $\theta_0 = X^\circ$ ”.
56
57

^[1] Lengths are in Å, angles in degrees, volumes in Å³. Average *NPT* MD (300 K, 1 bar) values at equilibrium for classical calculations, cell optimization for DFT.

[2] The brucite interlayer spacing is equal to $c/2$.

[3] Supercell with respect to the orthorhombic cell built from the trigonal unit cell according to $\mathbf{a}^* = \mathbf{a} - \mathbf{b}$ and $\mathbf{b}^* = \mathbf{a} + \mathbf{b}$. For theoretical results, the statistical uncertainty is lower than the given decimal precision, i.e. inferior to 0.01 Å for lengths and inferior to 0.1° for angles.

[4] in %; cf. Eq. (1).

Lattice parameters

The difference of lattice parameters derived from C-MD and DFT values with respect to the experimental values, and the difference of lattice parameters derived from C-MD with respect to the DFT values, is based on the lattice vectors ($\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3$):

$$\frac{\sum_{i=1}^3 \|\mathbf{u}_i - \mathbf{u}_{i \text{ ref}}\|}{\sum_{i=1}^3 \|\mathbf{u}_{i \text{ ref}}\|}, \text{ with } \|\mathbf{u}_1\| = a, \|\mathbf{u}_2\| = b, \|\mathbf{u}_3\| = c \quad (1)$$

As far as brucite is concerned, Zeitler et al.⁴⁹ observed that the bending term did not affect lattice parameters. From our *NPT*-ensemble simulations, the Mg-O-H bending term did not decrease the error on the lattice parameters: ClayFF-orig, ClayFF-MOH-110°, ClayFF-MOH-120° all lead to a reasonable 2.35-2.39% error with respect to experimental values, while ClayFF-MOH-100° results in a higher 4.00% error (Table 3).

The influence of the Al-O-H bending term on the gibbsite lattice parameters is shown in Table 3, along with the DFT results and experimental values. The respective values of a , b and c are not significantly influenced by the parameterization, however the value of θ_0 largely impacts the β angle. ClayFF-orig overestimates β by 5.9° with $\beta = 100.6^\circ$ instead of the experimental value $\beta = 94.5^\circ$ (Table 3). When applying the MOH term, the β angle is 93.8°, 91.5° and 97.9°, respectively, for $\theta_0 = 116^\circ$, $\theta_0 = 110^\circ$ and $\theta_0 = 100^\circ$. The total error with respect to experiment (Table 3) reduces from 5.42% (ClayFF-orig) to 3.66% ($\theta_0 = 100^\circ$), 3.29% ($\theta_0 = 110^\circ$) and 1.73% ($\theta_0 = 116^\circ$).

Proton transfer

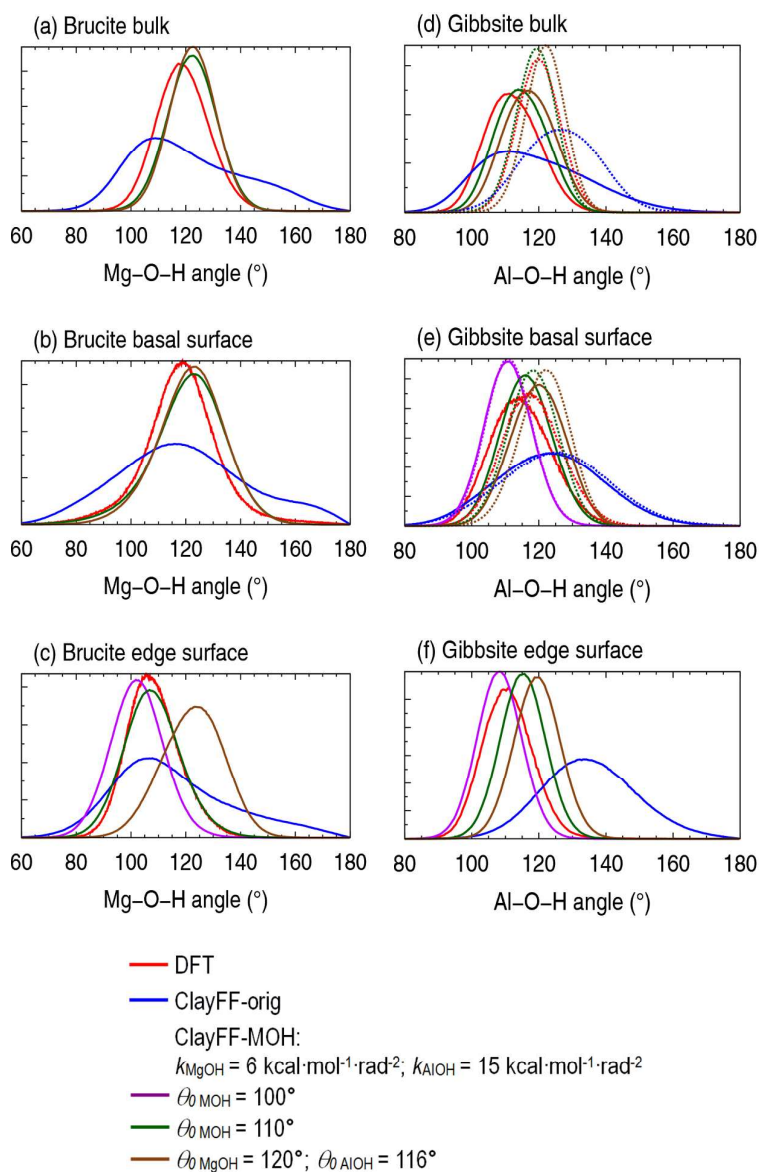

While no proton exchange was observed between surface hydroxyl groups and interfacial water molecules, multiple proton transfer events occurred at the edge surfaces of gibbsite and brucite in DFT simulations between an OH₂ group and a hydroxyl group of the neighboring mineral layers. Such events were not reported by the previous DFT-MD study of the gibbsite edge surface⁵⁸ probably because the repartition of the protons between edge sites, different from ours, did not favor proton hopping. Proton transfer is clearly enabled by physical interactions with interfacial water molecules since it was not observed in our test DFT-MD runs of the dry edge surfaces. The vast majority of these proton transfer events were very short incursions, typically of the order of magnitude of the O-H stretching vibration period, of one H_{OH2} atom on the neighboring O_{OH} atom, after which the proton returned back to the original O_{OH2} atom.

On the gibbsite edge surfaces ten or less of these proton hops were “successful”, in that the proton stayed on the neighboring O for more than 1 ps, while no successful hops occurred on the brucite edge surface. Proton hopping is illustrated via the time evolution of the distance between the protons and their two closest O atoms of the surface in Figure S7. A snapshot from the DFT-MD simulation of the gibbsite edge surface is shown in Figure 2c, illustrating the edge termination after a proton hopping event. To calculate MD-derived structural properties, for each configuration belonging to the DFT-MD trajectory, OH and OH₂ groups were identified based on a O-H distance cutoff of 1.2 Å, the optimal value determined from Figure S7.

Metal-O-H angle and O-H bond orientation of surface hydroxyl groups

Since the new M-O-H bending term is applied to angles, the metal-O-H angle (\angle MOH) distribution is the most immediate structural property to be influenced by its activation. The

ClayFF-orig parameterization greatly overestimates, typically by a factor of 2, the $\angle\text{MOH}$ standard deviation compared to the DFT results (Figure 3). As a general trend, the introduction of the M-O-H bending term systematically improves over the ClayFF-orig performance by reducing this standard deviation. As a result, the full widths at half maximum (FWHM) of the ClayFF-MOH distributions do not differ more than 3.0° from the respective DFT results.

1
2
3 **Figure 3.** Metal-O-H angle distributions for the brucite and gibbsite models. (d) and (e) OH_{ip}
4 and OH_{op} groups are represented by a solid and a dashed line, respectively.
5
6
7

8 Three-dimensional plots illustrate the probability—represented by a color range—to
9 find two of the three components of the O-H bond vector (Figures 4 and 5). For the bulk and
10 basal surface cells, the x and y components of the O-H vector are represented, with x and y
11 defining the basal plane. As far as the gibbsite and brucite edge surfaces are concerned, the
12 most relevant O-H components are x and z , x being the direction perpendicular to the edge
13 surface and z being the direction orthogonal to the basal plane (Figures 1 and 2). Due to the
14 similarity between ClayFF-MOH-100°, with $\theta_0 = 110^\circ$ and with $\theta_0 = 120^\circ$ (brucite) or
15 $\theta_0 = 116^\circ$ (gibbsite) in terms of the O-H orientational distributions, only the distributions
16 obtained by ClayFF-MOH-110° are shown in Figures 4 and 5 alongside the DFT and
17 ClayFF-orig results. Additionally, the density profiles of the O and H atoms of the gibbsite
18 and brucite edge hydroxyl groups are given in Figure S8.
19

24
25
26
27
28
29
30
31

32 As a consequence of the narrowing of all \angle MOH distributions, the orientations of all
33 O-H bond vectors become more localized leading to a much better agreement with the DFT
34 results. A strong and expected effect of the M-O-H bending term common to all surfaces is
35 the reduction of the extent of the O-H orientational distributions, resulting in more focused
36 spots.
37
38
39
40
41
42
43

44 *Brucite bulk and basal surface*

45
46 It was proven by neutron diffraction^{50,80,81} and confirmed later by static DFT
47 calculations⁸² that at high pressure, the brucite hydroxyl groups are not exactly oriented along
48 the threefold [001] axis, and that the deviation of the hydroxyl groups from this axis increases
49 with pressure. Experiments did not clearly show if this deviation occurs at atmospheric
50 pressure, but DFT simulations already predicted that at $T = 300$ K and $P = 1$ bar the most
51
52
53
54
55
56
57
58
59
60

probable orientation of the brucite bulk OH groups is exactly along the [001] axis and the probability decreases when the distance r from the axis increases⁸³ with r defined as:

$$r^2 = \text{OH}_x^2 + \text{OH}_y^2 \quad (2)$$

with OH_x and OH_y the components of the O–H bond vector along x and y directions, respectively. Our DFT-MD results confirm this preferred orientation of the bulk hydroxyl groups (Figure 4).

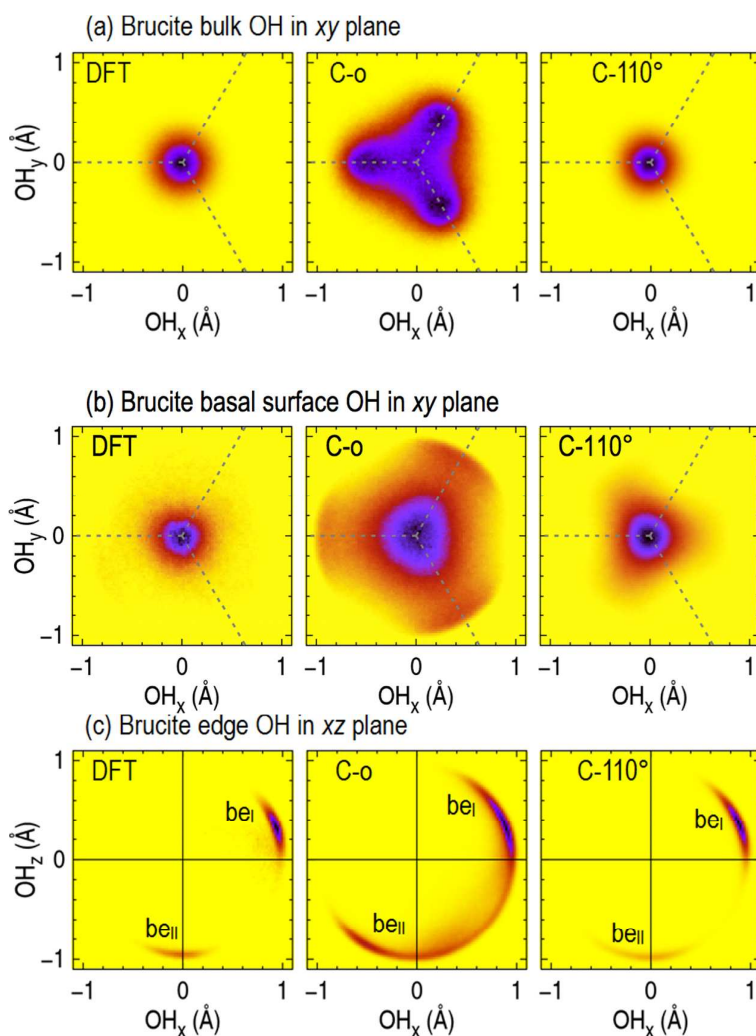

Figure 4. Orientation of brucite hydroxyl groups: distribution of the O–H bond vectors projected on the xy and xz crystallographic planes according to DFT (left), ClayFF-orig (center), and ClayFF-MOH-110° with $k = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ (right) MD simulations. The basal and the edge planes are oriented, respectively, parallel to xy and yz (Figures 1a,b). The color range from the lowest to the highest intensity is yellow, red, blue and black. The projections of the O–Mg vectors on the xy plane

1
2
3 are shown as gray dashed lines in (a) and (b). The regions of high intensity labeled
4 “be_x” (brucite edge) are discussed in the text.
5
6
7

8 The distribution also peaks at $r = 0$ for the basal surface OH groups, but it is slightly
9 more diffuse (Fig. 4b). Accordingly, the standard deviation of $\angle\text{MgOH}$ obtained from DFT-
10 MD ranges from 9.6° for the bulk to 13.9° for the hydrated basal surface, as illustrated in the
11 broadening of the distributions (Figures 3a and 3b). The hydration alone explains this
12 broadening, since the width of the dry basal surface distribution is identical to the bulk one.⁴⁹
13
14
15
16
17
18

19 The distribution derived from the ClayFF-orig simulations incorrectly predicts some
20 deviation of the O–H vector from the z -axis in the bulk. Indeed, the three regions of highest
21 intensity are away from the z -axis (Figure 4a). This explains why the angle corresponding to
22 the maximum of the ClayFF-orig $\angle\text{MgOH}$ distribution, $\angle\text{MgOH}^{\text{max}}$, is only at 109.4° ,
23 compared to the higher 118.3° DFT value (Figure 3a). However, for the basal surface
24 hydroxyl groups $\angle\text{MgOH}^{\text{max}} = 115.8^\circ$, closer to the 119.0° DFT value than in the bulk. This is
25 consistent with the most probable orientation of the O–H groups belonging to the basal
26 surface, which, contrary to the bulk, correctly coincides with the z -axis (Figure 4b).

31
32
33
34
35
36
37

38 *Brucite edge surface*

39

40 The brucite edge model in the current work differs from the one of Zeitler et al.⁴⁹ due to
41 the respective presence and absence of the OH₂ groups coordinated to edge Mg atoms, the
42 latter form being less likely (Table 1). This translates into a strong difference in the DFT
43 $\angle\text{MgOH}$ angular distribution with $\angle\text{MgOH}^{\text{max}} = 106.3^\circ$ (Figure 3c), 20° lower than for the
44 edge surface without OH₂ groups.⁴⁹ C-MD simulations with ClayFF-orig also result in
45 $\angle\text{MgOH}^{\text{max}} = 106.3^\circ$, and the ClayFF-MOH- 120° parameterization, with
46 $\angle\text{MgOH}^{\text{max}} = 124.1^\circ$, do not result in the best match with the DFT distribution. However,
47 using C-MD simulations with ClayFF-MOH- 110° and ClayFF-MOH- 100° result in
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 $\angle\text{MgOH}^{\text{max}}$ at $+0.6^\circ$ and at $+4.8^\circ$ from the value obtained by DFT-MD, respectively. The
4 FWHM of the distributions obtained from ClayFF-MOH- 110° (23.7°) and
5 ClayFF-MOH- 100° (22.2°) are close to the value obtained from DFT-MD (21.3°). The
6 distribution of the O-H vector in the xz plane resulting from the DFT calculations (Figure 4c)
7 peaks mostly along x in the “ be_I ” region, which represents 81% of the total intensity. This
8 spot is also present in the C-MD-derived distributions where it accounts for approximately
9 37% in the case of ClayFF-orig and 56% in the case of ClayFF-MOH- 110° models
10 (Figure 4c). Additionally, contrary to the ClayFF-orig results, ClayFF-MOH- 110° model
11 leads to the formation of very distinct “ be_I ” and “ be_{II} ” spots, similar to the DFT-produced
12 orientational distributions.
13

18
19
20
21
22
23
24

25 The Mg-O-H bending term restrains the O-H mobility along the z -axis, which results in
26 the most probable orientation at $r = 0$ in Figure 4a, similar to the DFT result, but more tightly
27 centered about the z -axis.
28
29
30
31

32 *Gibbsite bulk*

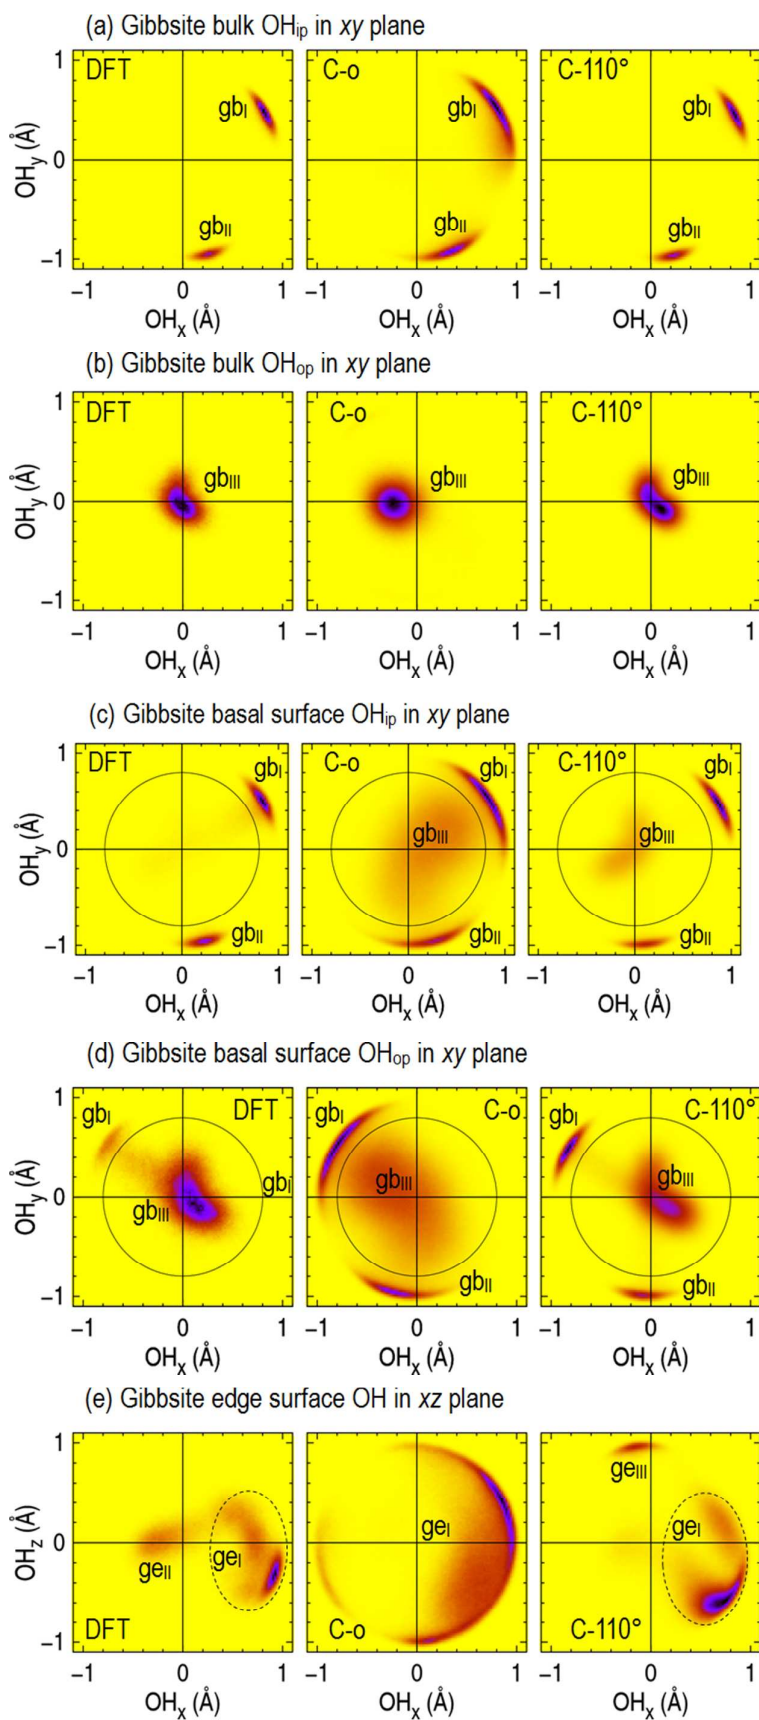

33
34
35 As proven experimentally⁵⁵ gibbsite hydroxyl groups adopt two orientations in the bulk
36 crystal (Figure 2) and can be sorted accordingly: the OH groups oriented almost entirely in the
37 xy plane are called OH_{ip} and the OH groups along the z direction are called OH_{op} . In the xy
38 plane OH_{ip} groups have two preferable orientations illustrated by the two spots labeled “ gb_I ”
39 and “ gb_{II} ” in Fig. 5a. Using the naming convention of Figure 2 (e and f), the spot “ gb_I ”
40 corresponds to the $\text{OH}_{\text{ip}1}$ and $\text{OH}_{\text{ip}2}$ groups, and the spot “ gb_{II} ” corresponds to the $\text{OH}_{\text{ip}3}$
41 groups, as confirmed by the ratio between the two intensities which is exactly 2:1. C-MD
42 simulations with ClayFF-orig and ClayFF-MOH- 110° correctly locate the maxima of the
43 “ gb_I ” and “ gb_{II} ” spots (Figure 5a), and their relative intensities, indicating that different OH_{ip}
44 groups keep their respective orientations during the C-MD run.
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 The addition of the M-O-H bending term in the case of the ClayFF-MOH-110° model
4 reduces the extent of these spots to bring them very close to DFT results (Figure 5a). The
5 OH_{op} groups are oriented slightly away from the z axis with the ClayFF-orig model (“gb_{III}”
6 spot in Figure 5b), but this is corrected in the ClayFF-MOH-110° model (Figure 5b). As
7 shown in Figure 3d, DFT calculations predict that the $\angle\text{AlOH}_{\text{op}}$ distribution is narrower
8 (FWHM = 15.1°) than the $\angle\text{AlOH}_{\text{ip}}$ distribution (FWHM = 20.0°). This could be explained by
9 the topology of the local H-bonding network. Indeed, OH_{op} groups donate H-bonds to the
10 neighboring layer, which are much stronger than the intralayer H-bonds donated by OH_{ip}
11 groups to OH_{op} groups. This also explains the cohesion of the gibbsite layers.^{55,56,84} The C-
12 MD simulations with the ClayFF-MOH model result in the $\angle\text{AlOH}$ angular distributions with
13 FWHM much closer to the DFT results, with FWHM \approx 19.3° for the OH_{ip} groups and
14 FWHM \approx 14.0° for the OH_{op} groups. The maxima are different for the ClayFF-MOH-110°
15 and ClayFF-MOH-116° sets of parameters, since the $\angle\text{AlOH}_{\text{op}}^{\text{max}}$ values differ from the DFT
16 results by 3.2° and 6.0°, respectively, while the $\angle\text{AlOH}_{\text{ip}}^{\text{max}}$ values differ from their respective
17 DFT results by 0.5° and 2.3°, respectively (Figure 3d).

37 *Gibbsite basal surface*

38
39
40 In the following, a basal surface hydroxyl group is considered “in-plane” if $r > 0.8 \text{ \AA}$, r
41 being defined in Eq. (2). According to the DFT calculations, the orientations of the hydroxyl
42 groups of the gibbsite basal surface are largely preserved, compared to the bulk, with most of
43 the O-H_{ip} vectors in the xy plane and most of the O-H_{op} vectors along the z axis (Figures 5c,d).
44 However, the probability of the in-plane orientation is 84%, which means that a small fraction
45 of the initially in-plane O-H_{ip} groups switch their orientation to out-of-plane (the
46 corresponding spot is hardly visible in Figure 5c). This is consistent with the ratio of
47 intensities of the spots “gb_I” and “gb_{II}” equal to 1.75:1 instead of 2:1 in the bulk, which means
48 that the reorientation to out-of-plane necessarily originates from the O-H_{ip1} and O-H_{ip2} groups.

54
55
56
57
58
59
60

1
2
3 In addition, a fraction of originally in-plane O-H_{ip} groups switch their orientation to
4 out-of-plane. Indeed, in Figure 5d the spot “gb_l” represents approximately 5% of the total
5 intensity. The distributions for $\angle\text{AlOH}_{\text{ip}}$ and $\angle\text{AlOH}_{\text{op}}$ of the basal surface are much closer to
6 each other (Figure 3e). According to DFT calculations, the values of $\angle\text{AlOH}_{\text{ip}}^{\text{max}}$ and
7 $\angle\text{AlOH}_{\text{op}}^{\text{max}}$ are 113.9° and 116.9°, respectively higher and lower than the corresponding bulk
8 values, while their FWHM are, respectively, 22.0 and 21.0°, both higher than the bulk values.

4 the xy and xz crystallographic planes according to DFT (left), ClayFF-orig (center),
5 and ClayFF-MOH-110° with $k = 15 \text{ kcal} \cdot \text{mol}^{-1} \cdot \text{rad}^{-2}$ (right) MD simulations. The
6 basal and edge planes are oriented, respectively, parallel to xy and yz (Fig. 2c,d).
7 The color range from the lowest to the highest intensity is yellow, red, blue and
8 black. The circle with $r = 0.8 \text{ \AA}$ represents the boundary between the “in-plane” and
9 “out-of-plane” orientations of the hydroxyl groups for the calculation of the
10 respective intensities. The regions of high intensity labeled “gb $_X$ ” (gibbsite bulk and
11 basal surface) and “ge $_X$ ” (gibbsite edge) are discussed in the text.
12
13
14
15
16
17

18 The smallest differences between the ClayFF-MOH and DFT results in terms of the
19 $\angle\text{AlOH}$ distributions for the basal surface are obtained by using the parameterization
20 ClayFF-MOH-110°, for which $\angle\text{AlOH}_{\text{ip}}^{\text{max}}$ and $\angle\text{AlOH}_{\text{op}}^{\text{max}}$ values are, respectively, only 2.2°
21 and 1.5° greater than their corresponding DFT values (Figure 3e). Similar to the bulk
22 comparisons, the $\angle\text{AlOH}_{\text{ip}}$ and $\angle\text{AlOH}_{\text{op}}$ distributions obtained by using the
23 ClayFF-MOH-116° model are shifted to higher angles (120° and 122°) than with $\theta_0 = 110^\circ$,
24 and their FWHMs are similar. Using the ClayFF-MOH-100° model, the distributions for the
25 two types of hydroxyl groups almost coincide; they are narrower (FWHM = 16.9°) and have
26 $\angle\text{AlOH}^{\text{max}} = 111.0^\circ$, which is lower than the DFT value.
27
28
29
30
31
32
33
34
35
36
37

38 As far as the hydroxyl orientation is concerned, fewer OH $_{\text{ip}}$ groups are oriented in the
39 basal plane than with DFT results. Indeed, the application of the ClayFF-orig model results in
40 a very large region “gb $_{\text{III}}$ ” spreading from $r = 0$ to $r \approx 0.8 \text{ \AA}$ and the probability of the in-plane
41 orientation—above $r = 0.8 \text{ \AA}$ according to our convention—is reduced to only 40%
42 (Figure 5c), less than a half of the DFT-derived probability. The application of the
43 ClayFF-MOH-110° model leads to an improved 55% probability for the in-plane orientation
44 (Figure 5c). The C-MD distribution of the O-H $_{\text{op}}$ vector in the xy plane shows two in-plane
45 spots “gb $_{\text{II}}$ ” and “gb $_{\text{III}}$ ” (Figure 5d) whose total intensity is 33% with the ClayFF-orig model,
46 and 25% with the ClayFF-MOH-110° model, i.e., a little closer to the DFT results.

Gibbsite edge surface

All gibbsite edge $\angle\text{AlOH}$ distributions are narrower than the ones for the basal surface (Figure 3f) due to hydroxyl groups involved in stronger H-bonds. The DFT-MD value of $\angle\text{AlOH}^{\text{max}} = 110.4^\circ$, has the closest C-MD counterpart of 108.4° , corresponding to the ClayFF-MOH- 100° model, while the values of $\angle\text{AlOH}^{\text{max}}$ obtained with $\theta_0 = 110^\circ$ and $\theta_0 = 116^\circ$ are 115.5° and 119.6° , respectively. The FWHM obtained from DFT-MD and C-MD with ClayFF-MOH are all very similar and fall in a narrow angular range between 15.6° and 17.5° . The DFT calculations predict that the O-H vector in the xz plane is primarily oriented along x (Figure 5e); the main spot of the distribution “ge_I” ranges from $\text{OH}_x \approx 0.3$ to $\text{OH}_x = 1.0 \text{ \AA}$, comprising 74% of the total intensity and reaches its maximum close to the x direction ($\text{OH}_x = 0.9$, $\text{OH}_z = -0.3$). The secondary lower intensity spot “ge_{II}” is located slightly away from the y -axis. With the ClayFF-orig model, the distribution also has its maximum close to the x -axis, but extends over 180° and to $r \approx 0.4 \text{ \AA}$ (Figure 5e). At the same time, the improved ClayFF-MOH- 110° model predicts a much more localized “ge_I” spot than with the ClayFF-orig model, comprising 80% of the total intensity of the distribution, close to the DFT results, and with a maximum at a slightly lower O- H_z value than its DFT counterpart (Figure 5e). The remaining intensity essentially lies in the spot “ge_{III}” along the z -axis, absent in the DFT distribution (Figure 5e).

Edge surface: OH₂ groups

Metal-OH₂ coordination

In the MD configurations at $t = 0$, all metal atoms (Mg or Al) belonging to the edge surface are coordinated to four bulk hydroxyl groups and two surface groups: one hydroxyl group and one OH₂ group (Figures 1c and 2c). During DFT-MD and C-MD simulations alike,

all hydroxyl groups remain attached to their respective metal (M) atoms during the entire simulation run. Desorption of OH₂ groups is unlikely, more so for the gibbsite edge as shown in Table 1. The M-OH₂ coordination number (CN) is given by the running coordination number (RCN) of the M-O_{OH₂+w} pair at $r \approx 3.0$ Å corresponding to the minimum between the first second peaks of the corresponding radial distribution function (RDF) (Figure 6). The first peak corresponds to OH₂ groups and the second peak corresponds to the sum of the neighboring OH₂ groups and the H₂O molecules of the aqueous interface.

Figure 6. Radial distributions functions (solid lines) and running coordination numbers (dashed lines) for the M-O_{OH₂+w} pairs of the (a) brucite and (b) gibbsite edge surfaces.

1
2
3
4
5 During the DFT-MD simulations, all adsorbed OH₂ groups remain connected to their
6 original Al atoms, since the Al-OH₂ CN is 1.0 (Figure 6). For C-MD simulations using the
7 ClayFF-orig model, only a portion of edge M atoms are coordinated to OH₂ groups, as
8 indicated by the Mg-OH₂ and Al-OH₂ CN being equal to 0.74 and 0.38, respectively. In recent
9 simulations of a montmorillonite edge model using ClayFF-orig, Newton et al.⁴⁶ also reported
10 M-O CN lower than 1.0, with Mg-OH₂ CN of 0.72 and Al-OH₂ CN of 0.25 or 0.81 depending
11 on the site. The brucite edge surface Mg-OH₂ coordination is, respectively, 0.43, 0.93 and
12 0.98 for ClayFF-MOH with $\theta_0 = 120^\circ$, $\theta_0 = 110^\circ$, and $\theta_0 = 100^\circ$ (Fig. 6a), thus the Mg-OH₂
13 coordination is very sensitive to θ_0 and the optimal value is $\theta_0 = 100^\circ$. The CNs for the
14 gibbsite edge surface Al-OH₂ groups are, respectively, 0.95, 0.96 and 0.98 for
15 ClayFF-MOH-116°, 110° and 100° (Figure 6), thus merely activating an explicit Al-O-H
16 bending term greatly improves the Al-OH₂ coordination by 0.6 units, compared to the DFT
17 results, and this improvement is not very sensitive to θ_0 .
18
19
20
21
22
23
24
25
26
27
28
29
30
31
32
33

34 Understandably, the inclusion of the M-O-H bending term does not significantly change
35 the distance corresponding to the first peak of the M-O_{OH₂+w} RDF maximum. For the brucite
36 edge it is located, respectively, at 2.13 and 2.29-2.31 Å for DFT and the two ClayFF
37 implementations, while for the gibbsite edge it is located, respectively, at 1.97 and
38 2.01-2.03 Å for DFT and the two ClayFF implementations.
39
40
41
42
43
44

45 In the structural analysis, the distinction between the bound OH₂ groups and interfacial
46 water molecules was based on the distance between the O atom and the closest M atom. If it
47 was less than 3.0 Å, the species was treated as an OH₂ group, otherwise the species was
48 considered as a water molecule of the interface.
49
50
51
52
53
54

55 For the gibbsite and brucite edge surfaces, as well as for the gibbsite basal surface, the
56 performances of the ClayFF-MOH-100° and ClayFF-MOH-110° models are comparable, in
57
58
59
60

1
2
3 terms of the surface $\angle\text{MOH}$ angle distributions and the M-OH_2 coordination, and they
4
5 produce better comparisons with the DFT results than those of the ClayFF-MOH-120° and
6
7 ClayFF-MOH-116° models. Therefore, the optimum value of the equilibrium angle is selected
8
9 as $\theta_{\text{AlOH}} = \theta_{\text{MgOH}} = 110^\circ$ and from hereon the “ClayFF-MOH-110°” set of parameters is
10
11 simply called “ClayFF-MOH”.
12
13

14 *H-O-H angle*

15
16
17
18 Given that the flexible SPC model was not only used to model water molecules, but also
19
20 the edge OH_2 groups, we need to evaluate the relevance of the H-O-H bending parameters,
21
22 thus $\angle\text{HOH}$ distributions of the OH_2 groups were determined for the brucite and gibbsite
23
24 edges (Figure 7). The DFT-MD-derived $\angle\text{HOH}$ distributions of the gibbsite edge OH_2 groups
25
26 coincide with that of the interfacial water molecules (Figure 7b). DFT calculations correctly
27
28 predict the mean liquid water $\angle\text{HOH}$ angle to be 105.9° , agreeing with the experimental value
29
30 of $106.1^\circ \pm 1.8^\circ$.⁸⁵ As far as the C-MD $\angle\text{HOH}$ distributions are concerned, the $\angle\text{HOH}^{\text{max}}$
31
32 values for OH_2 groups are within $0.8\text{-}1.3^\circ$ of the $\angle\text{HOH}^{\text{max}}$ values for water molecules, and
33
34 the FWHM are very close. From the DFT-MD simulation results, brucite edge OH_2 groups
35
36 have an angular $\angle\text{HOH}$ distribution clearly distinct from that of water molecules, with a larger
37
38 FWHM and an asymmetrical shape indicating at least two populations of OH_2 groups
39
40 (Figure 4a), resulting in an average $\angle\text{HOH} = 103.8^\circ$, which is 2.1° lower than the average
41
42 $\angle\text{HOH}$ value for water molecules. Interestingly, the ClayFF-orig and ClayFF-MOH $\angle\text{HOH}$
43
44 distributions of OH_2 groups are distinct. While the ClayFF-orig distribution is very similar to
45
46 that of molecular water, the ClayFF-MOH distribution has a lower $\angle\text{HOH}^{\text{max}}$ resulting in an
47
48 average angle of 102.6° and a broader width, both closer to the DFT distribution. These
49
50 results validate the application of the flexible SPC model to OH_2 groups.
51
52
53
54
55
56
57
58
59
60

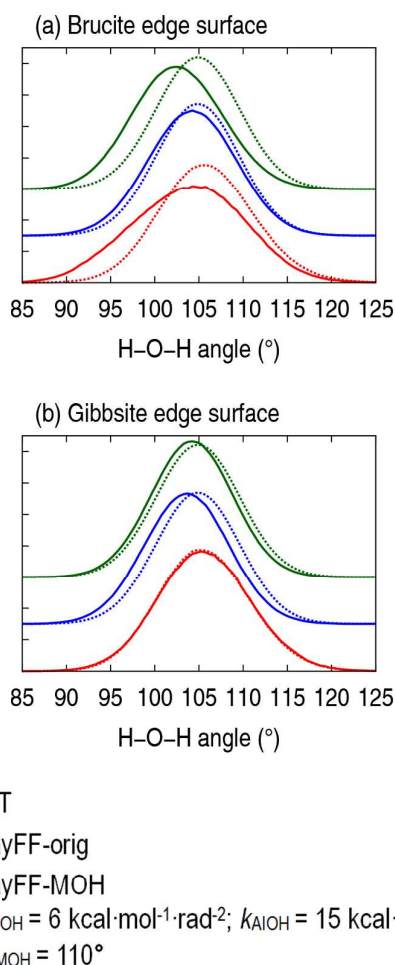

Figure 7. H-O-H angle distributions for the OH_2 groups (solid lines) on the edge surfaces of (a) brucite and (b) gibbsite. The distribution of the H-O-H angle of liquid water (dotted lines) is also given for comparison.

Orientation of surface OH_2 groups

Similar to our analysis of the surface OH orientation (Figures 4 and 5), the orientation of OH_2 groups on the edge surfaces of brucite and gibbsite is illustrated by the distribution of the O-H bond vectors projected on the crystallographic xz plane (Figure 8), with the O and H density profiles given additionally in Figure S9. Visualization of the distributions is facilitated by comparison with the DFT-MD snapshots in Figures 1c and 2c.

The DFT-MD-derived orientational distribution of the brucite edge surface O-H vectors reveals two main orientations comprising 84% of the total intensity: the spot “ be_1 ” (54%)

indicates an orientation predominately towards $+z$ direction, while the spot “be_{II}” (30%) is due to the O-H orientations towards x (Figure 8a). The ratio of intensities between the spots “be_I” and “be_{II}” is 1.8:1, and remains nearly the same for the ClayFF-orig results (1.9:1), but with more extended spot areas Figure 8a). With the ClayFF-MOH parameterization, secondary distributions decrease in intensity in favor of the two main orientations of which “be_I” is favored with a 4.5:1 ratio (Figure 8a).

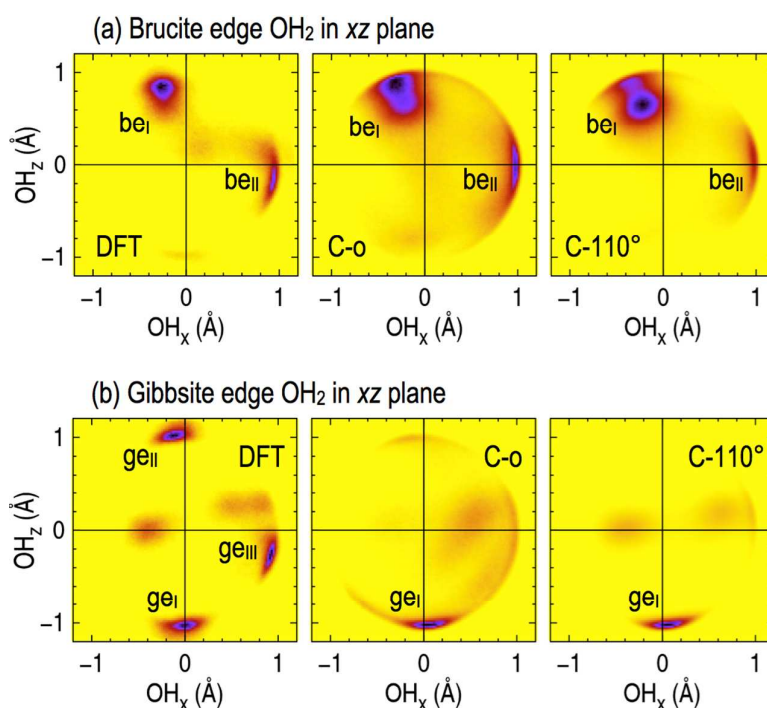

Figure 8. Orientation of gibbsite and brucite edge OH₂ groups: distribution of the O-H bond vectors projected on the xz plane. The color range from the lowest to the highest intensity is yellow, red, blue and black. “C-o” and “C-110°” stand for ClayFF-orig and ClayFF-MOH-110°, respectively.

For the gibbsite edge, the DFT-MD simulation produces three main orientations that account for 68% of the total intensity with comparable probabilities (Figure 8b). The spot “ge_I” (25%) is due to the O-H orientations towards $-z$, “ge_{II}” (22%) — towards $+x$, and “ge_{III}”

1
2
3 (21%) — towards +z. The spot “ge_I” is also present in the C-MD distributions and represents
4
5 34% and 44% with ClayFF-orig and ClayFF-MOH models, respectively. However, the spot
6
7 “ge_{II}” is almost absent from the C-MD distributions because it is largely due to the original
8
9 OH groups becoming OH₂ groups after of a proton hopping event as illustrated in Figure 2c.
10
11

12 13 14 15 CONCLUSIONS

16
17
18 Zeitler et al.⁴⁹ have earlier introduced a Mg-O-H bending term for ClayFF, $E_{\text{bend}} = k (\theta -$
19
20 $\theta_0)^2$, to better describe the structure and dynamics of hydroxyl groups at the surfaces of
21
22 brucite, Mg(OH)₂. Here we used a more systematic approach based on vibrational frequencies
23
24 and multiple structural criteria to determine the optimal values of the metal-O-H bending
25
26 parameters θ_0 and k . This work was performed for the Al-O-H bending term considering the
27
28 bulk crystal, the basal surface, and the (010) gibbsite edge surfaces. For consistency, the
29
30 procedure was also applied to the Mg-O-H bending term which was first parameterized by
31
32 Zeitler et al.,⁴⁹ based on the bulk crystal, the basal surface, and the (1 $\bar{1}$ 0) brucite edge
33
34 surface. The optimal values of θ_0 and k were then evaluated with MD simulations of the bulk
35
36 model and several hydrated surfaces, by comparing the results of classical MD simulations
37
38 with the original ClayFF-orig model and the improved ClayFF-MOH model to the results of
39
40 DFT MD simulations.
41
42
43
44

45
46 We determined the optimal value of the Al-O-H force constant and equilibrium angle to
47
48 be $k_{\text{AlOH}} = 15 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ and $\theta_{0,\text{AlOH}} = 110^\circ$. For the Mg-O-H bending term, we retained
49
50 the value of $k_{\text{MgOH}} = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ obtained by Zeitler et al.⁴⁹ Our analysis indicates that
51
52 ClayFF-MOH with $\theta_{0,\text{MgOH}} = 110^\circ$ provides the best results for the brucite edge surface and is
53
54 applicable to the bulk and basal surface, therefore $\theta_{0,\text{MgOH}} = \theta_{0,\text{AlOH}} = 110^\circ$ is selected. For
55
56 brucite, the use of ClayFF-MOH instead of ClayFF-orig results in a more properly localized
57
58
59
60

1
2
3 orientation of hydroxyl groups, in better agreement with DFT results, and strongly limits the
4
5 desorption of OH₂ groups at the mineral edge. These properties are also improved by the
6
7 ClayFF-MOH models for hydrated gibbsite interfaces where lattice parameters become closer
8
9 to the experimental values and the topology of hydrogen bonding on the basal and edge
10
11 surfaces are greatly improved.
12

13
14 Of course, all of these results assume that DFT calculations and the corresponding level
15
16 of quantum theory provide the best standard to judge the suitability of a classical approach
17
18 using ClayFF. The Mg-O-H and Al-O-H bending terms should be transferrable to most
19
20 layered mineral models, but the optimal values obtained here for metal hydroxides will have
21
22 to be evaluated for inclusion in mixed layer (e.g., T-O and T-O-T) models representative of
23
24 clay minerals. Although an extensive comparison of structural properties was provided here,
25
26 an analysis of the hydrogen bonding network and its statistical parameters as well as a
27
28 detailed analysis of the vibrational behavior of the bulk and surface hydroxyl groups of
29
30 brucite and gibbsite are beyond the scope of the current work and will be discussed elsewhere
31
32 (Fig. S10 of the supporting information illustrates the improvement brought by the addition of
33
34 the M-O-H bending term for reproducing the librational spectra of the edge O-H groups. A
35
36 similar parameterization of the M-O-H bending terms for Si and Al atoms in tetrahedral
37
38 coordination, essentially completing the current stage of ClayFF improvements aimed at
39
40 significantly more accurate and reliable modeling of clay particle surfaces and edges, will also
41
42 be reported separately.

Table 1. Energies of desorption at 0 K in vacuum of a water molecule from the brucite and gibbsite edge surfaces using DFT calculations,^[1] kcal·mol⁻¹.

	Brucite (1 $\bar{1}$ 0) edge	Gibbsite (010) edge	
Model A	18 Mg(OH)(OH ₂) ^[2]	8 Al(OH)(OH ₂) ^[2]	7 Al(OH)(OH ₂) 1 Al(OH ₂)(OH ₂)
Model B	17 Mg(OH)(OH ₂) 1 Mg(OH)	7 Al(OH)(OH ₂) 1 Al(OH)	7 Al(OH)(OH ₂) 1 Al(OH ₂)
$E_B + E_{H_2O} - E_A$	25.9	41.9	20.0

^[1] Model B was obtained from model A by removing one of the metal-coordinated OH₂ groups. Models were relaxed with a short 3 ps *NVT*-ensemble MD run at $T = 350$ K followed by geometry optimizations. Energies in kcal·mol⁻¹. E_{H_2O} is the energy of an isolated water molecule.

^[2] Models used in subsequent DFT calculations.

Table 2. Force Field Parameters

Nonbonded ^[1] : $E_{\text{nonbonded}} = \frac{q_i q_j}{4\pi\epsilon_0 r} + 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r}\right)^{12} - \left(\frac{\sigma_{ij}}{r}\right)^6 \right]$				
Species	Symbol	q (e)	ϵ (kcal·mol ⁻¹)	σ (Å)
Hydroxide Mg	mgh	1.0500	9.0298×10^{-7}	5.2643
Octahedral Al	ao	1.5750	1.3298×10^{-6}	4.2718
Hydroxyl O	oh	-0.9500	0.1554	3.1655
Hydroxyl H	ho	0.4250	0.000	0.0000
Water O	o*	-0.8200	0.1554	3.1655
Water H	h*	0.4100	0.0000	0.0000
$E_{\text{Morse}}^{\text{bond}} = D_0 [1 - e^{\alpha(r-r_0)}]^2$				
Bond	D_0 (kcal·mol ⁻¹)	α (Å ⁻¹)	r_0 (Å)	
oh-ho ^[2]	132.2491	2.1350	0.9572	
$E_{\text{quadratic}}^{\text{bond}} = k(r - r_0)^2$				
Bond	k (kcal·mol ⁻¹ ·Å ⁻²)	r_0 (Å)		
o*-h* ⁷¹	554.13	1.0000		
$E_{\text{quadratic}}^{\text{angle}} = k(\theta - \theta_0)^2$				
Angle	k (kcal·mol ⁻¹ ·rad ⁻²)	θ_0 (°)		
h*-o*-h* ^{1,73}	45.770	109.47		

^[1] Parameters of Cygan et al.¹; $\sigma_{\alpha\beta} = 1/2 (\sigma_\alpha\sigma_\beta)$ and $\epsilon_{\alpha\beta} = (\epsilon_\alpha\epsilon_\beta)^{1/2}$.

^[2] Two different sets were parameterized by Greathouse et al. for dioctahedral and trioctahedral clays,⁷¹ and the set for trioctahedral clays was found to be optimal here.

Table 3. Brucite and gibbsite lattice parameters rescaled to the unit cell using DFT, ClayFF-orig and ClayFF-MOH.^[1]

Brucite ^[2]						
	Exp. ³⁰	DFT	ClayFF

^[1] Lengths are in Å, angles in degrees, volumes in Å³. Average *NPT* MD (300 K, 1 bar) values at equilibrium for classical calculations, cell optimization for DFT.

^[2] The brucite interlayer spacing is equal to $c/2$.

^[3] Supercell with respect to the orthorhombic cell built from the trigonal unit cell according to $\mathbf{a}^* = \mathbf{a} - \mathbf{b}$ and $\mathbf{b}^* = \mathbf{a} + \mathbf{b}$. For theoretical results, the statistical uncertainty is lower than the given decimal precision, i.e. inferior to 0.01 Å for lengths and inferior to 0.1° for angles.

^[4] in %; cf. Eq. (1).

Figure captions

Figure 1. Brucite small models. (a) Bulk model obtained by DFT geometry optimization; (b)-(d) DFT-MD snapshots. The models are oriented according to the coordinate system shown in (a). H₂O molecules not coordinated to Mg atoms are hidden in (c) for clarity.

Figure 2. Gibbsite small models and hydroxyl groups types. (a) Bulk model obtained by DFT geometry optimization. (b)-(d) DFT-MD snapshots. The models are oriented according to the coordinate system shown in (a). H₂O molecules not coordinated to Al atoms are hidden in (c) for clarity. The proton in gray was bonded to the atom O_i at $t = t_0$ and was transferred to the atom O_{ii} during the DFT-MD run. The six types of hydroxyl groups oriented in the basal plane (OH_{ip}, in-plane) and out of the basal plane (OH_{op}, out-of-plane) are shown in (e) and (f) for the structures obtained by DFT geometry optimizations.

Figure 3. Metal-O-H angle distributions for the brucite and gibbsite models. (d) and (e) OH_{ip} and OH_{op} groups are represented by a solid and a dashed line, respectively.

Figure 4. Orientation of brucite hydroxyl groups: distribution of the O–H bond vectors projected on the xy and xz crystallographic planes according to DFT (left), ClayFF-orig (center), and ClayFF-MOH-110° with $k = 6 \text{ kcal}\cdot\text{mol}^{-1}\cdot\text{rad}^{-2}$ (right) MD simulations. The basal and the edge planes are oriented, respectively, parallel to xy and yz (Figures 1a,b). The color range from the lowest to the highest intensity is yellow, red, blue and black. The projections of the O–Mg vectors on the xy plane are shown as gray dashed lines in (a) and (b). The regions of high intensity labeled “be_x” (brucite edge) are discussed in the text.

I. RESULTS FROM STATIC CALCULATIONS

In Figs. S1-S6, the mean differences between the DFT and ClayFF-MOH results in terms of wavenumbers and O-H orientations are represented against the Metal-O-H bending term parameters θ and k , for every value of θ within the 90-130° range ($\delta\theta = 1^\circ$), and for every value of k within the 0-40 kcal·mol⁻¹·rad² range ($\delta k = 1^\circ$).

For each DFT-derived mode u , the ClayFF-MOH-derived mode v_0 corresponding to the maximum value of the overlap, S_{u,v_0} , was found (S1). The overlap S_{u,v_0} was then used to weight the difference in wavenumbers $|\bar{\nu}_u - \bar{\nu}_{v_0}|$ (S2).

$$S_{u,v_0} = \max_{\text{modes } v} \left\{ \sum_{i=1}^{N_{\text{atoms}}} \mathbf{e}_{u,i} \cdot \mathbf{e}_{v,i} \right\} \quad (\text{S1})$$

$$\langle |\Delta\bar{\nu}| \rangle = \frac{1}{\sum_{i=1}^{N_{\text{modes}}} S_{u,v_0}} \sum_{i=1}^{N_{\text{modes}}} S_{u,v_0} |\bar{\nu}_u - \bar{\nu}_{v_0}| \quad (\text{S2})$$

The average difference in O-H orientation was defined as:

$$\langle |\Delta O-H \text{ orientation}| \rangle = \frac{1}{N_{\text{OH}}} \sum_{i=1}^{N_{\text{atoms}}} \arccos \left(\frac{\overrightarrow{OH}_{u,i} \cdot \overrightarrow{OH}_{v,i}}{\|\overrightarrow{OH}_{u,i}\| \cdot \|\overrightarrow{OH}_{v,i}\|} \right) \quad (\text{S3})$$

All atoms are taken into account in the averaging for the bulk models. Only the outermost slice of atoms of each type are taken into account for the surface models: metal atoms, oxygen and hydrogen atoms of hydroxyl groups, as well as oxygen and hydrogen atoms of OH₂ groups for the edge surface models.

In order to define optimal areas in the (θ_0, k) plane, each point I of the graphs in Figs S1-S5, defined by its coordinates $(\theta_0, k, \langle |\Delta \bar{\nu}| \rangle)$ or $(\theta_0, k, \langle |\Delta O-H \text{ orientation}| \rangle)$, is assigned a small circle if:

$$\langle |\Delta A_I| \rangle - SEM(|\Delta A_I|) < \langle |\Delta A_{I_0}| \rangle - SEM(\Delta A_{I_0}) \quad (S4)$$

with SEM the standard error of the mean and I_0 the point of the graph corresponding to the minimum value of the mean difference in wavenumbers or in O-H orientation across the domain defined by $\theta_0 \in [90; 130^\circ]$ and $k \in [0; 40 \text{ kcal} \cdot \text{mol}^{-1} \cdot \text{rad}^{-2}]$.

II. COMPLEMENTARY MD-DERIVED RESULTS

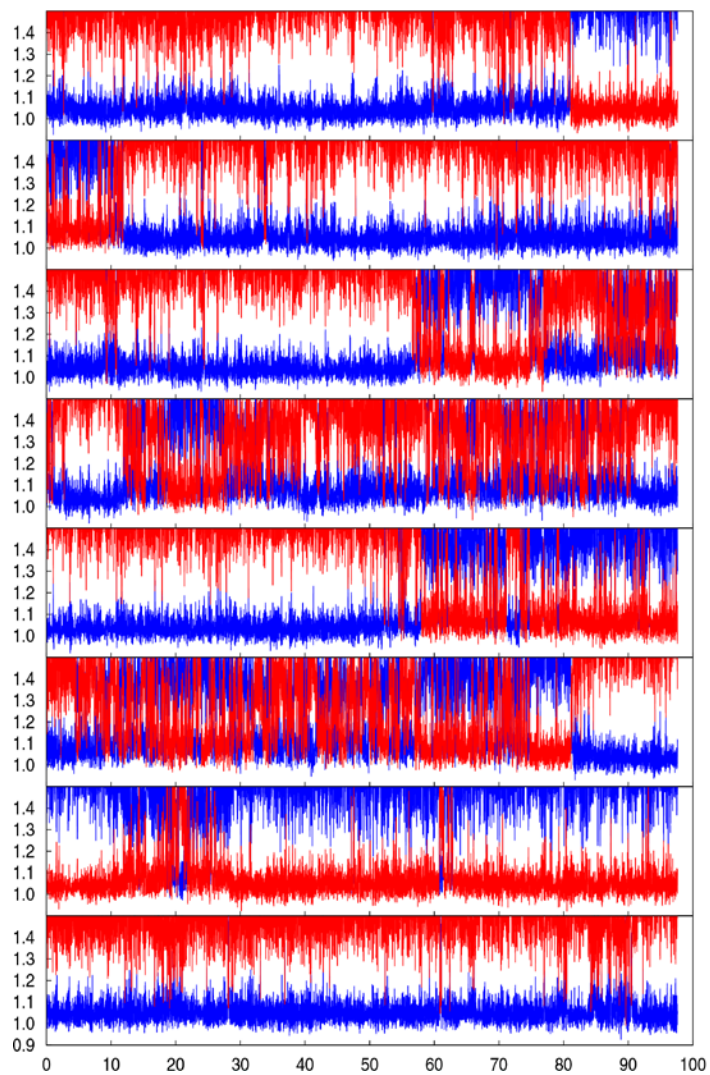

Figure S7. Evolution of the distance (\AA) between a proton and its 2 closest O neighbors on the edge surface of gibbsite as a function of time (ps), for a selection of 8 protons, during the DFT-MD run.

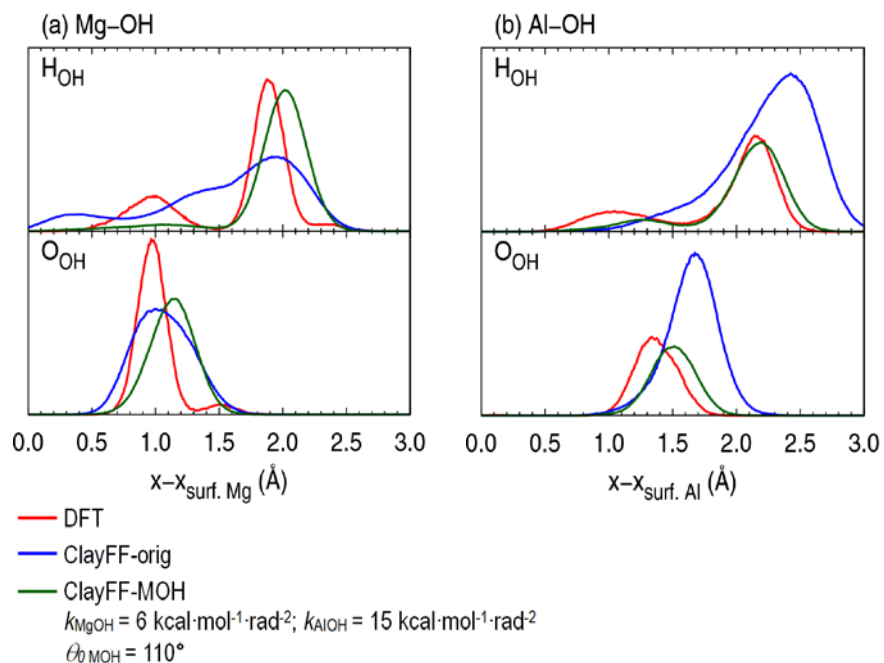

Figure S8. Density profiles of the atoms of the edge hydroxyl groups. (a) brucite edge surface and (b) gibbsite edge surface. x is normal to the edge plane.

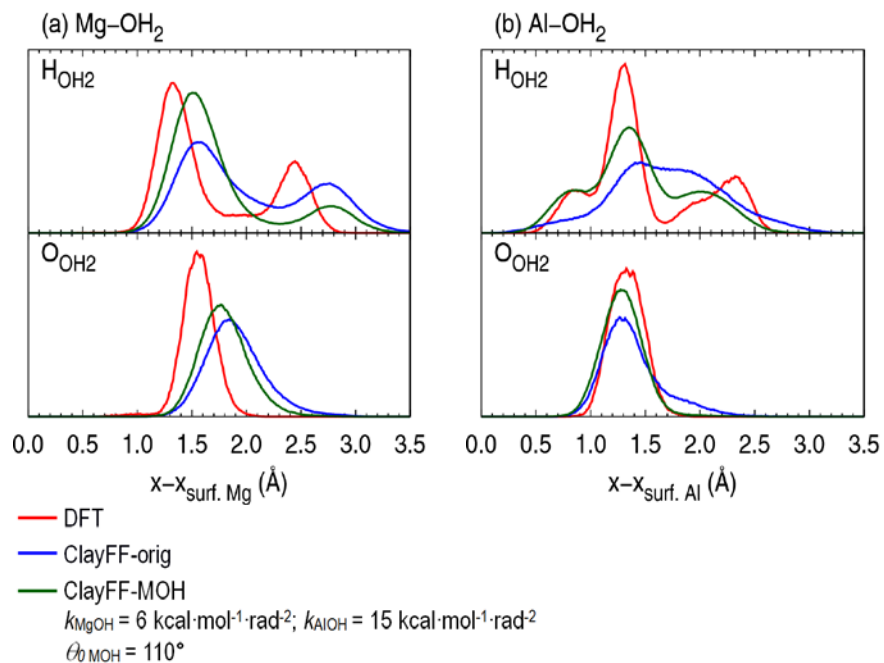

Figure S9. Density profiles of the atoms of the edge OH₂ groups. (a) brucite edge surface and (b) gibbsite edge surface. x is normal to the edge plane.

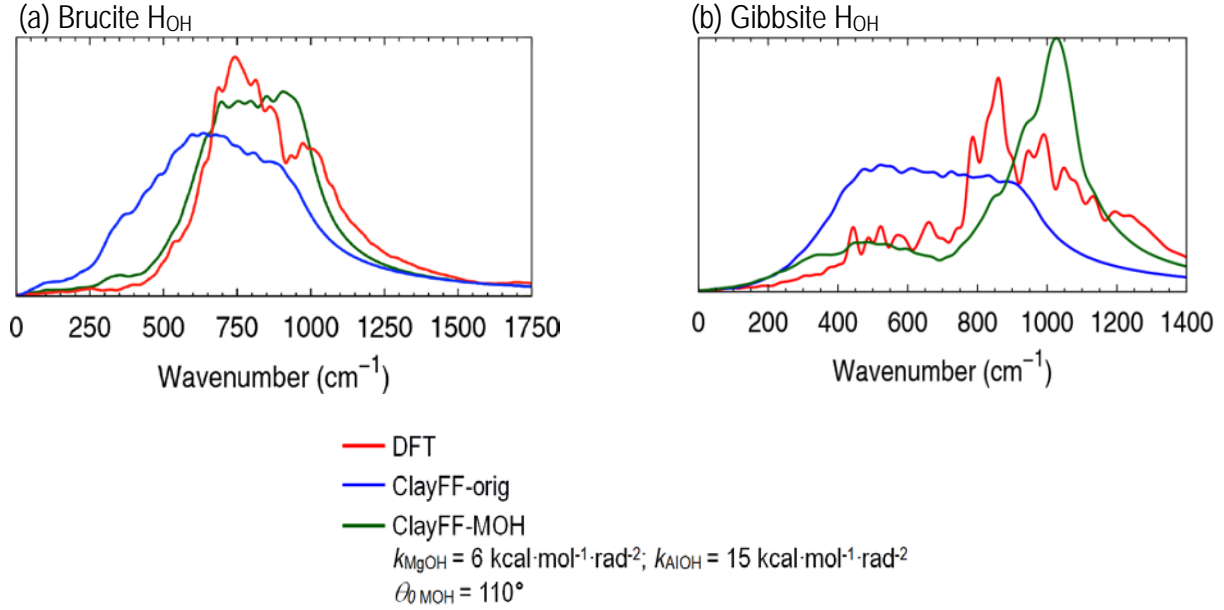

Figure S10. Vibrational density of states of the hydrogen atoms of the OH groups belonging to the edge surfaces of brucite and gibbsite.

In Fig. S10 above the vibrational density of states is calculated from the velocity autocorrelation function $f(t)$ of the hydrogen atoms. The function $f'(t)$ is then obtained by windowing $f(t)$, with the upper bound set to $t_{\text{win}}=1$ ps:

$$f'(t) = f(t) \sqrt{1 - \frac{t}{t_{\text{win}}}} \quad (\text{S4})$$

The vibrational density of states $P(\nu)$ is then calculated:

$$P(\nu) = \int [(f'(t) \cos(\omega t))^2 + (f'(t) \sin(\omega t))^2] dt \quad (\text{S5})$$

III. Implementation of the new M-O-H ClayFF term in LAMMPS

The Metal-O-H angle potential must be added to the ClayFF force field by keeping active the Metal-O and Metal-H nonbonded—Lennard-Jones and coulombic—interactions.

In the LAMMPS software, an angle potential can act on an A-B-C trio independently of the existence of A-B and B-C bonds. The M-O-H trios have to be generated beforehand by the user and have to be listed in LAMMPS under the “Angles” section of the data file with the following syntax: “*ID type atom1 atom2 atom3*”, with one line per trio. In the input file, the line “angle_style harmonic” must be included. Angle coefficients are defined either in the input file with “angle_coeff *type k θ_0* ” or in the data file with “*type k θ_0* ” under the “Angle Coeffs” section. Since no M-O bond is defined in ClayFF, LAMMPS will keep turned on the Lennard-Jones and coulombic interactions between M and O atoms, and between M and H atoms, which is the wanted behavior.

If MD software is used where M-O-H angles can only be generated automatically from the M-O and O-H connections, then the user has to ensure the software is able to turn on the nonbonded M-O and M-H terms—while keeping turned off the intramolecular H-H and O-H nonbonded terms for water molecules.
